## **Abstract**

A technique for detecting large hydrometeors at high altitudes is described here and applied to UARS MLS (Upper Atmosphere Research Satellite Microwave Limb Sounder) 203-GHz radiance measurements at tangent pressures between 200 and 46 hPa. At these tangent pressures the radiances remain optically thin and cloudy-sky radiances are brighter than normal clear-sky cases. Unlike infrared/visible cloud observations, the 203-GHz radiances can penetrate most ice clouds and are sensitive to ice crystals of convective origin. Rough *IWC* retrievals are made near the tropopause using estimated size distributions from in-situ convective studies. The seasonal mean *IWC* observed at 100 hPa reaches 20 ppmv or more over convective centers, dominating the total water content. Convectively lofted ice therefore appears to be hydrologically significant at the tropical cold point. *IWC* is well correlated spatially with  $RH_i$  (relative humidity with respect to ice) at 100 hPa during both the dry (January-March) and moist (July-September) periods.

## 1. Introduction

Clouds near the tropical tropopause layer (TTL) play an important role in the water budget in the Earth's upper troposphere. However, lack of cloud and water vapor measurements has been a major limitation in understanding what this role is. In particular, the role of overshooting, convective clouds near the tropical tropopause has been contested in the literature (e.g., Newell and Gould-Stewart 1981; Danielsen 1982; Dessler 1998; Sherwood and Dessler 2000; Holton and Gettelman 2001).

Measuring cloud ice at the tropopause altitudes has been challenging. Passive nadir-viewing microwave techniques do not have sufficient resolution to resolve vertical distributions of cloud ice near tropopause heights. These observations have been limited to column measurements such as cloud liquid water path (*LWP*) and ice water path (*IWP*) (e.g., Evans et al. 1998; Liu and Curry 2000; Zhao and Weng 2002). On the other hand, satellite infrared (IR) and visible limb-scan techniques (e.g., Wang et al., 1995) are dominated by diffuse (thin cirrus) clouds rather than small, opaque clouds which may nonetheless contribute significant ice content. Documentation of significant convective lofting of ice to the tropical tropopause has been limited to a few in-situ cases (e.g., Knollenberg et al. 1993).

Millimeter and sub-millimeter limb techniques offer a new opportunity for observing cloud ice near the tropopause, which are complementary to IR/visible nadir sensors in many aspects. In particular, microwave limb techniques have gained appreciable vertical resolutions to detect high clouds at different altitudes. The long horizontal path lengths of limb sounding become very useful for surveying tropopause cloud ice with more frequent intersections of tall and narrow clouds than that from nadir

sounders. Moreover, microwave radiation can penetrate through most ice clouds and provide cloud mass information, without being limited by cloud temperature, surface emission and multiple scattering that often cause problems in other remote sensing techniques.

This paper describes a cloud detection and ice water content (*IWC*) retrieval technique, which has been applied to the UARS MLS (Upper Atmosphere Research Satellite Microwave Limb Sounder) 203-GHz radiances. The retrieval makes use of cloud-induced radiances ( $\Delta T_{cir}$ ) at high tangent heights ( $h_t$ ) and involves a two-step calculation:  $\Delta T_{cir}$  to *hIWP* (ice water path along line-of-sight) and *hIWP* to *IWC*. We focus on the MLS *IWC* and cloud occurrence frequency (CF) measurements for two special periods when dynamics in the TTL differ substantially: the dry (January-March 1992) and wet (July-September 1992) phases of the “tape recorder” phenomenon in the lowermost tropical stratosphere (Mote et al. 1996). MLS measures tropopause cloud ice and water vapor (Read et al. 2004) near simultaneously, which makes these data very unique for TTL studies.

## **2. MLS 203-GHz Observations**

### *a. UARS MLS Experiment*

UARS MLS is a passive instrument with three double-sideband radiometers near 63, 183 and 203 GHz, measuring temperature (T), H<sub>2</sub>O, O<sub>3</sub> and ClO profiles in the middle atmosphere (Barath et al. 1993; Waters 1993; Froidevaux et al. 1996; Livesey et al. 2003). There are 30 spectral channels in the 183-GHz radiometer and 45 channels in the 203-GHz radiometer that cover spectral ranges: 183.1-186.5 GHz and 200.1-206.4

GHz, respectively. Compared to nadir-scanning operational microwave radiometers, the vertical field-of-view (FOV) of the MLS 203-GHz radiometer is narrower: ~3 km at the tangent point. The horizontal resolutions are 7 km across and ~300 km along the line-of-sight (LOS).

The vertical plane of MLS scan is  $90^\circ$  from the satellite direction of motion and the antenna step-scans the atmospheric limb from ~90 km to the surface in 65.5 s during normal operation. The scan interval varies from ~3 km in the stratosphere/troposphere to ~5 km in the mesosphere. MLS radiances lack coherence when they hit clouds because of the relatively large spatial separation between adjacent measurements (vertically by ~3 km and horizontally by 15 km). With such sparse sampling MLS cannot adequately resolve deep convective clouds in either dimension. The MLS horizontal resolution is also limited by the smearing along the LOS (~300 km). MLS latitudinal coverage ranges from  $34^\circ$  in one hemisphere to  $80^\circ$  in the other as a result of the  $57^\circ$  orbital inclination and the instrument viewing direction. UARS performs a  $180^\circ$ -yaw maneuver 10 times per year to allow alternate observations of high latitudes every ~36 days. The MLS 203-GHz radiometer was fully operational (producing ~1300 profiles per day) between September 1991 and December 1994 before the number of daily profiles was reduced. The 183-GHz radiometer stopped collecting data in April 1993 after 18 months of successful operation. Beside the normal scan mode, MLS was also operated occasionally with a limb-tracking mode in which the FOV points at a fixed  $h_t$  (usually ~18 km).

The MLS 183- and 203-GHz radiometers together provide nearly-collocated water vapor and cloud ice in the UT/LS (upper troposphere and lower stratosphere) region. The 183-GHz radiances have best sensitivity to water vapor in the lower

stratosphere (Pumphrey 1999) and in the upper TTL region (Read et al. 2004). On the other hand, the 203-GHz channel provides the best water vapor sensitivity at 464-147 hPa (Read et al., 2001). However, these water vapor retrievals suffer from cloud contamination when scattering of ice particles is strong. Cloud-induced radiances are best detected with the 203-GHz channel and can be used for cloud ice retrieval.

### *b. Cloud Signatures in Limb Radiances*

Clouds can affect MLS radiances at all  $h_t$  below the cloud top but the cloud effects can vary substantially with frequency and  $h_t$ , which yield unique limb radiance measurements in many cases. The best channel for cloud detection is near the spectral window (i.e., 203 GHz for MLS) where the radiances are least affected by H<sub>2</sub>O and O<sub>3</sub>. Figure 1 shows MLS radiance measurements at ~203 GHz during limb-scan and limb-tracking operations. In the limb-scan case [Figure 1a], clear-sky radiance profiles are mostly clustered in a narrow band with clear upper and lower bounds. Water vapor variabilities cause most of the radiance spread within the band. A few measurements outside the clear-sky band are indicative of thick-and-dense clouds where the cloud-induced radiance  $\Delta T_{cir}$  (the difference from the clear-sky limit) can be as much as 30 K at  $h_t=12$  km and -130 K at  $h_t < 5$  km. The instrument noise (~0.09 K) is generally negligible compared to these cloud effects. Lacking contrasts at  $h_t=8-12$  km, cloud effects become difficult to distinguish from clear-sky variability. Thus, for the best cloud detection, we have to rely on limb radiances in optically thin (at high  $h_t$ ) or optically thick (at low  $h_t$ ) situations. To study cloud ice near the tropopause, this paper uses the optically-thin radiances exclusively.

In the 18-km limb-tracking observations [Figure 1(b)], clear and cloudy radiances can be distinguished by correlation among adjacent measurements, which exhibits very different characteristics in the two cases. Clear-sky radiances vary smoothly along the orbit due to changes in tangent pressure ( $P_{\text{tan}}$ ),  $\text{H}_2\text{O}$  and  $T$ . Except for the sharp discontinuities caused by MLS pointing adjustments, the coherence among neighboring clear-sky radiances is very high. On the other hand, cloudy radiances lack point-to-point coherence but exhibit generally high brightness than the normal background as a whole. In this example the peak  $\Delta T_{\text{cir}}$  reaches as high as  $\sim 20$  K at latitudes between  $15^\circ\text{N}$ - $20^\circ\text{N}$ .

The limb  $\Delta T_{\text{cir}}$  near the tropopause could arise from narrow thick-and-dense towers (e.g., deep convective core) or from extensive cirrus outflows. Because MLS limb measurements are separated by 15 km horizontally, the correlation between adjacent  $\Delta T_{\text{cir}}$  measurements could be used to infer the sizes of cloud systems. Poor point-to-point correlation suggests that the clouds be likely of deep convective type since their sizes are typically 10-50 km, whereas extensive cirrus anvils would produce a better point-to-point correlation. We have browsed many days of the limb-tracking data and found that MLS-sensitive clouds at the tropopause heights are mostly of convective type with a few cases blended with broad warmer-than-normal features in the brightness temperature. Long-lived, extensive thin cirrus do not contribute significantly to the MLS  $\Delta T_{\text{cir}}$  because of low  $IWC$ s and small ice particles. This assertion is also in line with the result from the Mie calculation (Appendix-A), where only large (100-300  $\mu\text{m}$ ) ice particles can produce significant volume extinction at 203 GHz. The appearance of a significant number of such large particles is generally associated with strong deep convection.

In principle ice emission and scattering can both cause the excess radiances at  $h_t > 12$  km. Scattering directs the radiation from below and above into LOS. The scattered radiance from below brings in brightness temperature radiation higher than the normal background whereas the one from above brings in colder radiation (cosmic background + downward radiation). In addition to scattering, cloud ice emission itself adds radiation to the normal background. If  $\Delta T_{cir}$  is dominated by ice emission, cloud ice would behave like a gas species and the  $\Delta T_{cir}$ - $hIWP$  relation is independent of particle size distributions (PSD). If the process is dominated by scattering, the  $\Delta T_{cir}$ - $hIWP$  relation depends on PSD, shape and ice density, as well as surface emission and cloud distribution. For the coarse sampling with UARS MLS, it is not practical to retrieve  $IWC$  from  $hIWP$  on a single scan because the required spherical homogeneity assumption. To overcome this limitation, we make regional averages of  $hIWP$  measurements on a monthly or seasonal basis, in which cloud variabilities at short temporal and spatial scales are hopefully washed out and the spherical homogeneity assumption may be applied to the region. In this study the region for averaging  $hIWP$  is defined as a  $5^\circ \times 10^\circ$  latitude-longitude box, where typically 40 samples are collected for a period of one month in the tropics. A similar retrieval approach was used on SAGE II (Stratospheric Aerosol and Gas Experiment II) data where cloud occurrence frequency is averaged to overcome undersampling problems by the limb technique (Wang et al. 1995).

### *c. Clear and Cloudy-Sky Separation*

The methods for cloud detection generally fall into two categories: (i) empirical approaches based on clear-cloudy sky contrasts among adjacent measurements, and (ii)

model approaches to compute clear-sky limits based on radiative-transfer (RT) models. In either case, the algorithm needs to be robust and reliable enough for exception handling like missing data, unknown atmospheric background, and erroneous instrument pointing. For IR limb sounding, efforts have been spent to distinguish clouds from aerosols (Kent et al. 1993). For MLS, cloud detection relies largely on accuracy of  $P_{\text{tan}}$  and clear-sky radiance calculations.

This study chooses to use the RT method for determining clear-sky radiance and compute the 203-GHz  $\Delta T_{\text{cir}}$  for each  $P_{\text{tan}}$ . The clear-sky RT model is the same as used in Read et al. (2001) for upper-tropospheric H<sub>2</sub>O retrieval, which is initialized with MLS v5 retrievals for T,  $P_{\text{tan}}$ , stratospheric H<sub>2</sub>O and O<sub>3</sub> (Livesey et al., 2003). In the troposphere the NCEP (National Centers for Environmental Prediction) T is used. For the 203-GHz radiance, the sensitivity to H<sub>2</sub>O increases with  $P_{\text{tan}}$  at 100-300 hPa, showing a dynamic range of 50-110 K at 200 hPa between very dry and very moist situations. This generally means poor ability for detecting clouds. To model clear-sky radiance limits at  $P_{\text{tan}}=100$ -200 hPa, we assume  $RH_i=110\%$  for tropospheric H<sub>2</sub>O, which accounts for ~50% supersaturation cases according to the exponential power law deduced from aircraft data (Sprichtinger et al., 2002). This  $RH_i$  threshold has a small impact on the radiance limit at 100 hPa because of insensitivity to H<sub>2</sub>O at this level. This is shown in Read et al. (2001) and also in Figure 1a, where the 203-GHz radiance at 100 hPa is dominated by the dry-continuum emission.

The  $\Delta T_{\text{cir}}$  uncertainty depends on how well the clear-sky radiance can be modeled. As discussed in Read et al. (2001), the empirically-derived 203-GHz dry and wet continuum coefficients have effectively absorbed most of the systematic biases in the

NCEP T. As a consequence, the T biases do not have as much impact on the modeled radiance limit as one would expect. Figure 2a shows the  $\Delta T_{cir}$  deduced from the data set in Figure 1a using the RT method. The sharp division in numbers of measurements between positive and negative  $\Delta T_{cir}$  at high  $h_t$  suggests that the RT model method works reasonably well in separating between clear and cloudy-sky radiances. The edge of division is blurred at  $P_{tan} = 200-300$  hPa, reflecting increasing error in cloud detection with the RT method. Figure 2b shows the 100-hPa  $\Delta T_{cir}$  histogram from six months of the data. The clear-sky  $\Delta T_{cir}$ , fitted well to a Gaussian distribution, has a bias of 0.9 K and a standard deviation of 0.9 K at 100 hPa, due to a combination of error in  $P_{tan}$  and T and uncounted atmospheric variabilities in  $H_2O$ ,  $O_3$  and  $HNO_3$ , etc. False cloud detection, which could introduce a bias to  $\Delta T_{cir}$ , is determined by the portion of the Gaussian distribution with  $\Delta T_{cir} > 3$  K. For the 3-K threshold, false detection can cause biases of 0.03 K in  $\Delta T_{cir}$  and 0.9% in CF. These errors drop sharply to 0.001 K and 0.025%, respectively, when the 4-K threshold is used.

### 3. Cloud Ice Retrieval

Figure 3 outlines the MLS cloud detection and retrieval algorithm scheme for measurements at high  $h_t$ . For cloud ice retrieval, we use a cloudy-sky RT (Appendix A) to obtain the  $\Delta T_{cir}-hIWP$  relations. Unlike the conventional definition of nadir cloud column,  $hIWP$  represents the integral along MLS LOS, which is oriented more horizontally than vertically.

*a. The  $\Delta T_{cir}$ - $hIWP$  relation*

The  $\Delta T_{cir}$ - $hIWP$  relations are  $h_t$  dependent and the RT model with cloud scattering assumes spherical ice particles and PSDs from McFarquhar and Heymsfield (1997) (hereafter MH97). Because of the penetration ability of the 203-GHz radiation, the calculated  $\Delta T_{cir}$ - $hIWP$  relation is affected little by the  $IWC$  profile used. Cloud self-extinction and air attenuation is considered in the  $hIWP$  calculation, which can become critical for low- $h_t$  situations where cloud self-extinction is strong.

The retrieval starts by first converting  $\Delta T_{cir}$  to  $hIWP$  with the modeled  $\Delta T_{cir}$ - $hIWP$  relation. This is applied independently to each measurement at  $h_t$  before they are averaged into monthly or seasonal composites. As shown in Figure 4 the modeled  $\Delta T_{cir}$ - $hIWP$  relation is  $h_t$ -dependent, varying from  $\sim 7 \text{ K kg}^{-1} \text{ m}^2$  at  $\sim 15 \text{ km}$  to  $\sim 11 \text{ K kg}^{-1} \text{ m}^2$  at  $11 \text{ km}$ . The  $h_t$  dependency is caused primarily by the height-dependent PSDs in MH97.

*b. IWC Retrievals*

The converted  $hIWP$  are then averaged into 8  $P_{tan}$  bins (44.4, 58.2, 76.3, 100, 131, and 172 hPa) and  $5^\circ \times 10^\circ$  (latitude  $\times$  longitude) grid boxes. For each grid box,  $IWC$  is retrieved from the averaged  $hIWP$ s using the *onion-peeling* technique and outputted at four pressure levels at 76, 100, 131, and 172 hPa. The false detection bias (0.03 K) in  $\Delta T_{cir}$  would yield a  $\sim 0.05 \text{ mg/m}^3$  bias in  $IWC$  at 100 hPa. The retrieved  $IWC$  is a regional mean (including both clear and cloudy cases), which is different from the regional mean single-cloud  $IWC$ . The latter is the  $IWC$  averaged only for cloudy cases that measures average ice mass carried by a single cloud. The two quantities are related by CF, a quantity that is also derived from MLS radiance measurements.

### *c. IWC - $\Delta T_{cir}$ Relation at 100 hPa*

Because most deep convective clouds in the tropics top out around 100 hPa, the *hIWP-to-IWC* inversion may not be needed at the top level. Cloudy-sky RT calculations [Figure A.3] show that the 100-hPa  $\Delta T_{cir}$  is approximately proportional to *IWC* at 100 hPa and the *IWC -  $\Delta T_{cir}$*  relation is nearly linear ( $\sim 1.5 \text{ mg/m}^3/\text{K}$ ) for  $\Delta T_{cir}$  less than  $\sim 30 \text{ K}$ . Since the observed  $\Delta T_{cir}$  are mostly less than 30 K at this level, it is valid for most cloud cases at 100 hPa to use the linear *IWC- $\Delta T_{cir}$*  relation for the conversion. Like the *hIWP- $\Delta T_{cir}$*  conversion, the *IWC- $\Delta T_{cir}$*  conversion suffers from the scaling error due to uncertainties about ice PSD, shape and density.

## **4. Initial Results**

The initial studies with MLS cloud ice measurements are focused on the dry (January-March) and moist (July-September) phases of the lower stratospheric "tape recorder" (Mote et al. 1996). Figures 5 and 6 compare maps of T, CF, *IWC*, H<sub>2</sub>O and *RHi* (relative humidity w.r.t. ice) at 100 hPa for the two periods in 1992. MLS v702 H<sub>2</sub>O (Read et al. 2003) is used to help diagnose/interpret *IWC* morphology. The *RHi* data is derived from MLS H<sub>2</sub>O volume mixing ratio (*vmr*) and NCEP temperature. The following analyses are focused on the geographical distributions and temporal variations of cloud ice in relation to T, H<sub>2</sub>O, and *RHi* at 100 hPa.

### *a. Dry Period (January-March 1992)*

During the dry period the 100-hPa *IWC* and CF exhibit clear maxima near the intertropical convective zones (ITCZ). The CF map agrees well with overshooting cloud morphology observed by the TRMM Precipitation Radar (Alcala and Dessler, 2002). The

maximum 100-hPa *IWC* in this seasonal average reaches  $\sim 3 \text{ mg/m}^3$ , which coincides with the CF peak ( $\sim 20\%$ ). Deep convective regions over South America and South Africa have less ice mass at 100 hPa with a maximum of  $\sim 2 \text{ mg/m}^3$  in *IWC* and  $\sim 20\%$  in CF. Over northern Australia and the southeast Asian archipelagos, there are some scattered occurrences with *IWC* around  $1\text{-}1.5 \text{ mg/m}^3$ .

The comparison with NCEP T shows that the cold (less than 198 K) regions are associated with the high 100-hPa *IWC*s but shifted slightly in latitude. Generally speaking, the region with temperature less than 198 K exhibits good symmetry about the equator and covers a much larger area than cloud ice. Despite the latitudinal shift, the longitudinal temperature variations (2-4 K) correlate well with the modulations of *IWC*. These characteristics are consistent with comparisons between MLS *IWC* with UKMO (UK Met Office) temperature (not shown).

At 100 hPa the *IWC* patterns differ noticeably from the  $\text{H}_2\text{O}$  *vmr*, especially in the southern subtropical Pacific where the high *vmr* belt is  $\sim 5\text{-}10^\circ$  southward of the *IWC* band. This shift between these two maximum locations implies the water vapor band is even farther away from the center of the cold temperature region in the central Pacific. The vapor *vmr* and cloud ice distributions at 100 hPa appear to have larger deviation over oceans than over land masses. However, the 100-hPa *IWC* patterns are found to correlate significantly better with MLS 147-hPa vapor *vmr* (not shown) where no obvious latitudinal shift is found in the southern Pacific.

In the Northern Hemisphere, there exists a low ( $\sim 2.3 \text{ ppmv}$ )  $\text{H}_2\text{O}$  *vmr* band around  $\sim 25^\circ\text{N}$  latitude across most longitudes with a slightly wider region over the Central America. This low *vmr* band also exists but appears wider at 147 hPa where the

moist band in the Southern Hemisphere shrinks and vanishes eventually at 215 and 316 hPa (not shown). The similar H<sub>2</sub>O distribution repeats during the period of January-March 1993. Over South America and South Africa, *IWC* and H<sub>2</sub>O *vmr* are well correlated but the locations of their maxima remain slightly shifted.

There is a better correlation between the *IWC* and *RH<sub>i</sub>* patterns at 100 hPa. However, there are some noticeable differences. For example, the peak *RH<sub>i</sub>* is found slightly north of the *IWC* maximum over South America, but aligned closely over South Africa. The 100-hPa *RH<sub>i</sub>* over the central Pacific is lower than those over land masses, whereas the opposite is true for the 100-hPa *IWC* for land-ocean differences. This appears in line with the finding of Sherwood (2002) that continental cumulus clouds have smaller crystal sizes, which would reduce their microwave scattering potential but increase their ability to moisten the tropopause region. However, caution is required when interpreting *RH<sub>i</sub>* here since it depends on NCEP temperatures. The average *RH<sub>i</sub>* is far below saturation at 100 hPa near the cloudy regions, varying between 25% and 40%, which is mostly due to the biases in MLS H<sub>2</sub>O retrieval (Read et al. 2003) and NCEP temperature (Randel et al. 2000).

*b. Moist Period (July-September 1992)*

During the moist period [Figure 6], the 100-hPa *IWC* pattern is dominated by the contributions from Indian monsoons and typhoon systems in Southeast Asia. Deep convective systems produce up to 8 K modulations in NCEP T cross the 25°N latitude band. The UKMO T indicates similar but somewhat smaller (4-6 K) perturbations at this latitude band (not shown). Again, the region with 100-hPa temperature lower than 200 K,

centered on the equator, covers most of the tropics and subtropics. The cold region is strongly perturbed by the Asian and American monsoons, pushing the envelope north to  $\sim 40^\circ\text{N}$ . Like in the dry period, longitudinal temperature variations seem well correlated with *IWC*.

Compared to the Asian monsoon, the Central American monsoon contributes much smaller *IWC* at 100 hPa. A similar amount of contribution is found over central Africa and western Pacific. Unlike in the dry period, the correlation between *IWC* and  $\text{H}_2\text{O}$  *vmr* at 100 hPa is generally good in most places, particularly near the Indian and Central American monsoons, showing peaks of  $3 \text{ mg/m}^3$  in *IWC* and  $\sim 5 \text{ ppmv}$  in  $\text{H}_2\text{O}$  *vmr*. Away from the deep convective zones, there is no obvious dry latitude band in the Southern Hemisphere (winter hemisphere) where the *vmr* decreases monotonically with latitude.

Overall, *IWC* in the wet period correlates better with  $RH_i$  at 100 hPa than with the other fields. The monsoons over India/Asia, Central America and Africa produce  $RH_i$  of 25-40% at 100 hPa with the highest  $RH_i$  over Indian/Asian region. There are strong latitudinal  $RH_i$  and temperature gradients north of the Indian monsoon as deep convective activity pushes far north from the equator. The cloud ice maxima over Japan, Central America and Africa coincide with high  $RH_i$ , but not necessarily with peak  $RH_i$  values.

### *c. Seasonal Variations*

The temporal behavior of MLS *IWC* and  $\text{H}_2\text{O}$  is dominated by seasonal variations, and exhibits strong latitude-dependence as shown in Figure 7. Here, the 100-

hPa *IWC* and H<sub>2</sub>O data are limited to the early period of UARS mission (September 1991 - April 1993) when both MLS 183- and 203-GHz radiometers were operating.

MLS 100-hPa  $\Delta T_{cir}$  (used as a cloud ice proxy) resembles the seasonal cycle of deep convective activity in the middle troposphere very well, varying around the equator within  $\pm 10^\circ$  in latitude. Rough conversion from  $\Delta T_{cir}$  to *IWC* at 100 hPa can be carried out with the 1.5 mg/m<sup>3</sup>/K factor based on the in-situ studies [Figure A.3]. The average 100-hPa *IWC* between 30°S-30°N is  $\sim 0.07$  mg/m<sup>3</sup>, not varying significantly during 1991-1997. This *IWC* value would yield an equivalent  $\sim 0.7$  ppmv water vapor in the same region, a significant portion of the total water budget in the tropical tropopause. The *IWC* seasonal variation is consistent with MLS H<sub>2</sub>O at 147 hPa, which is expected for the moistening from convective outflows at the bottom of the TTL. However, the latitudinal spread of the 147-hPa H<sub>2</sub>O is slightly wider than that of the 100-hPa *IWC*.

The seasonal variation of the 100-hPa H<sub>2</sub>O differs substantially from that of the 100-hPa cloud ice. This level is affected both by convection (Dessler 2002) and by the stratospheric circulation (Yulaeva et al 1994), and the H<sub>2</sub>O seasonal cycle reflects variations in both of these processes. The interactions between convection and synoptic circulations in the UT/LS region are complex, and depend on many variables, such as microphysical properties of the clouds as well as ambient relative humidity (Sherwood 2002; Sherwood and Dessler 2003; Dessler and Sherwood 2003). A comprehensive explanation and quantification of the distribution of these variables will have to await further theoretical and observational studies.

The moisture variation exhibits a very different pattern when expressed in  $RH_i$  instead of H<sub>2</sub>O *vmr*. Because of the strong dependence of  $RH_i$  on temperature, most of

the  $RH_i$  variations result from the latitudinal and seasonal variations of temperature. The temperature error must be considered seriously in this analysis because of nonlinearity of the Clausius-Clapeyron equation. A 1-K error in temperature would yield a relative error of 17% in  $RH_i$  at 100 hPa, and therefore, conclusions based on  $RH_i$  variations should be treated with caution.

## 5. Discussion

Scattering calculations based on the MH97 PSDs [Appendix A] suggest that most of the 203-GHz  $\Delta T_{cir}$  at tropopause heights are induced by ice particles of diameters between 100-300  $\mu\text{m}$ . These are much larger than sizes expected for subvisible cirrus formed in situ (Jensen et al. 1996), but are typical for clouds near deep convective cores where the updraft velocity is strong enough to lift large particles to the upper troposphere. Thus, we believe that the MLS cloud ice represent mostly deep convective clouds, which are beyond, and therefore complementary to, the capability of IR and visible techniques. This inference is also consistent with the observed localization of the ice distribution relative to that of relative humidity, and with the large ice mixing ratios inferred.

However, large uncertainty arises when converting MLS  $\Delta T_{cir}$  to  $IWC$  because the 203-GHz radiances are only sensitive to ice particles of the large-size mode that may contribute only a half of total  $IWC$  [Appendix A]. Assumptions about ice particle size and shape distributions are therefore critical to connect ice scattering sensed by MLS to the ice mass. As shown in Appendix A, a bimodal PSD can complicate the  $IWC$  retrieval by having more degrees of freedom in PSD.

MLS  $IWC$  uncertainty is mostly in scaling error, not bias, as a result of the  $\Delta T_{cir}$ -to- $hIWC$  conversion. It should not have large impact on the correlation and distribution

studies as shown above. Table 1 summarizes the estimated scaling differences for the  $\Delta T_{cir}$  -*IWC* conversion at 100 hPa with different PSDs. The derived *IWC* can differ by a factor of 2-3 depending on the PSD used. The MH97 PSD parameterization was developed from aircraft observations of deep convective outflows during the Central Equatorial Pacific Experiment (CEPEX). The MH97 work incorporates effects of size-dependent bulk density of ice particles in their parameterization in terms of mass-equivalent spheres. It produces clear bimodal distributions for large *IWC* near the tropopause. However, the dataset lack measurements inside convective cores. In the case of strong turbulence/mixing during convective updraft, the PSD inside convective cores may differ substantially from those measured in the outflows. Strong overshooting cases can yield updraft velocities as high as  $20 \text{ ms}^{-1}$  (e.g., Geerts et al., 2000), with which ice particles can be readily mixed over several km. As a result, deep convective clouds at 100 hPa may have a PSD similar to those at lower altitudes. Such PSD mixing between vertical cloud layers, as shown in Table 1 for the  $-60^{\circ}\text{C}$  and  $-75^{\circ}\text{C}$  cases, would result 30% differences in *IWC* from, which is relatively small compared to the differences from using different PSD parameterizations.

PSD can be height-dependent and sometimes *IWC*-dependent as suggested by MH97. Liu and Curry (1998) studied essentially the same CEPEX dataset but came up with a slightly different PSD parameterization. The primary difference between MH97 and Liu-Curry parameterizations is the assumption about particles with diameter  $< 100 \mu\text{m}$ , which turns out to be critical for *IWC* retrievals at 203 GHz. The Liu-Curry parameterization produces a smaller mass-mean diameter for the same temperature and hence a would-be larger MLS *IWC*. Heymsfield et al. (2002) compiled a parameterization

by fitting height-dependent gamma distributions to in-situ measurements in the tropics and subtropics at  $T > -55^{\circ}\text{C}$ . The MLS *IWC* from this parameterization at  $-60^{\circ}\text{C}$  yields the same result as one from the MH97 PSD despite different mass-mean diameters. The Heymsfield (2002) result at  $-75^{\circ}\text{C}$  may be negligible because it is extrapolated from the measurements at lower altitudes. Lack of reliable PSD information renders large scaling error as high as 100-200% for the *IWC* at 100 hPa. In addition, Evans and Stephens (1995) argued that assumptions about ice particle shape and density are as equally important as PSD under extreme conditions. It is not clear, however, what are the statistical orientations of different particle shapes and how significant the radiance polarization differences can be at 203 GHz. As a promising note, a recent study showed an encouraging agreement between collocated in-situ and remotely-sensed (radar) *IWC* measurements with biases  $< 20\%$  (Sayres, 2003). This result has important implications to both passive and active cloud remote sensing methods since they all depend on PSD assumptions. It is readily to find a large number of co-located satellite measurements for calibrating *IWCs* obtained between from space radar and from passive sensors, but the radar-insitu matches are difficult to find and remain very sparse. We anticipate that the accuracy for remotely-sensed *IWC* will continuously be improved as more in-situ *IWC* measurements are collected from future sub-orbital or under-flight platforms. Nevertheless, reducing uncertainties associated with particle size, shape and ice density remains as a major challenge in future cloud observations.

Despite the existing uncertainty, MLS *IWC* observations from the 203-GHz radiances are unique and no previous estimates exist for global convective cloud ice at the tropopause. The cloud ice maps and seasonal variations contain useful information for

improving our understanding of the processes in the TTL. Because of the penetrative ability of microwave radiation, the 203-GHz limb radiance demonstrates an adequate dynamic range for measuring thick-and-dense clouds in the TTL, particularly those from deep convection. Thus, cloud inhomogeneity becomes less a problem than in optically-saturated cases, and the  $hIWP-\Delta T_{cir}$  relation depends little on cloud location along LOS.

The existence of significant cloud ice in the TTL has an important implication to understanding of mass transport at high altitudes. The "slow ascent" models like Holton and Gettelman [2001], Jensen et al. [2003], and others have been emphasizing transport controlled by large-scale flows, but did not consider mass transport by convection above the lowest levels of the TTL, except for only the effects of convection on the temperature structure of the TTL. The MLS observations, which despite the large uncertainties, are unique, and show that convection is important throughout the TTL. This suggests that the "slow ascent" models need to be modified to take into account the existence of convection extending throughout the TTL.

## 6. Summary and Future Work

The initial *IWC* retrievals from the 203-GHz radiances, together with MLS water vapor measurement and NCEP temperature data, reveal many interesting features related to interactions between deep convective clouds and tropopause dynamics. These results can be summarized as follows:

1. The average 100-hPa *IWC* between 30°S-30°N is  $\sim 0.07 \text{ mg/m}^3$  during 1991-1997, which is obtained assuming the MH97 PSD in cloud scattering calculations. This *IWC* would yield  $\sim 0.7 \text{ ppmv}$  for equivalent water vapor in the same region, a significant portion of the total water budget in the tropical tropopause. Seasonal *IWC*

means may reach up to 30 ppmv vapor equivalent over convective areas, far exceeding the vapor mass at this level. However, these *IWC* values must be treated with caution due to potential scaling error of 200-300% from PSD and particle shape uncertainties. But even with a factor of three error, peak *IWC* values must dominate the total water content at 100 hPa over some deep convective regions, confirming the importance of convectively lofted ice to the water budget up to the tropical cold point

2. There is a generally good correlation between *IWC* and  $RH_i$  at 100 hPa in both seasonal extremes. However, ice distributions are more localized but often offset from  $RH_i$  maxima, suggesting that deep convection is the dominant source of the observed local  $RH_i$  variability, as expected from radiative transfer arguments. Ice maxima over land areas tend to be moister than those over oceans, suggesting dynamical or microphysical differences between the cloud systems.
3. In general, MLS *IWC* distribution patterns correlate positively with the water vapor *vmr* at 100 hPa except near the southern Pacific during the dry period (e.g., January-March 1992), where the *vmr* peak is located 5-10° south of the *IWC*. Better correlation is found when comparing the 100-hPa *IWC* to the 147-hPa H<sub>2</sub>O *vmr*.

A new MLS instrument, to be launched on NASA Aura satellite in June 2004, will have the frequency channels similar to UARS MLS with a number of additions near 118, 190, 240, 640 GHz and 2.5 THz. The broader bandwidths and high-rate  $h_i$  sampling (every ~0.4 km) from the new instrument will provide much improved data in the upper troposphere (Waters et al. 1999). In particular, we plan to use the Aura 240 and 640 GHz measurements to study the 100-hPa cloud ice, and hopefully to reduce uncertainty by comparing them to *IWC* measurements from CloudSat 94-GHz Cloud Profiling Radar

(CPR) (due launch in 2005). Aura MLS and CloudSat CPR, flying in formation as part of NASA's "A" train, will have comparable footprint with samples taken within 7 min to each other. The new data will help to resolve some issues not adequately addressed with the UARS data.

### **Acknowledgments**

We thank Dr. Joe Waters for valuable comments and Dr. Gloria Manney for providing the NCEP and UKMO temperature data. AED and SCS acknowledge an EOS Interdisciplinary Science grant to the University of Maryland and Yale University. This research was performed at the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration (NASA).

## Appendices

### Appendix A. Cloudy-sky radiative transfer (RT) model

The RT model that we use to calculate MLS 203-GHz cloudy radiances is briefly described in the following. The radiative transfer equation we solve along the LOS can be written as

$$\frac{dT_b}{ds} = -\beta_e T_b + \beta_a \hat{T} + \beta_s T_{scat} \quad (\text{A1})$$

where  $s$  is distance along the LOS,  $T_b$  is microwave radiance in Kelvin, and  $\beta_e$ ,  $\beta_a$ , and  $\beta_s$  are total volume extinction, absorption and scattering coefficients, respectively, in unit of  $m^{-1}$  (e.g., Ulaby *et al.* 1981). The first source function  $\hat{T}$  represents emission and is equal to air temperature  $T$  under the Rayleigh-Jeans approximation. The second source function  $T_{scat}$  accounts for the radiances scattered into the LOS by clouds. For simplicity, we neglect the polarization properties of cloud scatterers, and assume spherical ice particles. The atmosphere is divided into spherically-stratified layers with vertically-varying gases and cloud variables (temperature, density, ice water content, etc.).

Equation (A1) can be evaluated by separate downward and upward integrals. For the *downward* path, the integration is carried out from the top of model atmosphere to the tangent point (or the surface if the tangent height is below the surface), and the *upward* path integration is carried out from the tangent point (or the surface) to the top of the atmosphere.

The scattering processes are assumed to be independent (or incoherent) among different cloud hydrometers so that the total scattered radiances can be expressed as the

sum of contributions from different particles (van de Hulst, 1981). Cloud ice particles are also assumed made of pure water with density  $\rho_{ice} = 0.91 \text{ g/cm}^3$ , and uncertainties in  $\rho_{ice}$  will cause a scaling error in the modeled  $\Delta T_{cir} - hIWP$  relation. The Mie theory is applied to calculate phase functions and scattering coefficients for each particle size. The model uses the MH97 PSD parameterization and includes only ice particles between 0-4000  $\mu\text{m}$  in diameter.

Figure A1 shows relative contribution to  $IWC$  and volume extinction/scattering coefficients ( $\beta_{c_e}/\beta_{c_s}$ ) at 203 GHz from unit size bin with a MH97 PSD. Since  $IWC$  and scattering are proportional to respectively third and sixth moment of the PSD, the bimodal size distribution plays a key role in partitioning  $IWC$  between those from diameters  $< 100 \mu\text{m}$  and those from  $> 100 \mu\text{m}$ . As indicated by the relative  $\beta_{c_s}$  contribution from unit size bins, or  $d\beta_{c_s}/dr$ , the 203-GHz radiances provide better sensitivity at diameters  $> 100 \mu\text{m}$ . However, these large particles may not dominate the total  $IWC$  according to the MH97 PSD parameterization. In this example the ratio of the 203-GHz sensitivity, i.e.,  $\beta_{c_e}(2r < 100\mu\text{m}) : \beta_{c_e}(2r > 100\mu\text{m})$ , is 1:7, whereas the ratio of  $IWC(2r < 100\mu\text{m}) : IWC(2r > 100\mu\text{m})$  is nearly 1:1.

The source functions  $T_{scat}$  are calculated using an iterative approach for each cloud layer (e.g., Wilheit et al, 1982). These are localized sources and therefore we may assume plane-parallel geometry for the calculations. Figure A2 illustrates the coordinates for the  $T_{scat}$  calculation, where the scattering volume is placed at the origin, the Z-axis is zenith, and the LOS lies in the Y-Z plane with angle  $\Theta$  from zenith and  $\Phi=90^\circ$  from X-axis. The incident radiance  $T_b$  with zenith angle  $\Theta'$  is a function of  $\theta$ ,  $\phi$  and  $\Theta$ , where

angles  $(\theta, \phi)$  are the angular coordinates with respect to the LOS. Since the incident  $T_b$  is only a function of  $\Theta'$  for the plane-parallel atmosphere, the expression for  $T_{scat}$  can be simplified to the following

$$T_{scat}(\Theta) = \frac{1}{2} \int_0^\pi P(\theta') \bar{T}_b(\theta') \sin \theta' d\theta' \quad (\text{A2})$$

and

$$\begin{aligned} \bar{T}_b(\theta') &= \frac{1}{2\pi} \int_0^{2\pi} T_b(\theta', \phi') d\phi' \\ &= \frac{1}{2\pi} \int_0^{2\pi} T_b(\Theta') d\phi' \end{aligned}$$

where  $\theta'$  is the scattering angle between  $\Theta$  and  $\Theta'$  and  $\phi'$  is the azimuth angle that lies in the plane perpendicular to the LOS. The angle  $\Theta'$  can be expressed in terms of  $\theta'$ ,  $\phi'$  and  $\Theta$  as

$$\cos \Theta' = \vec{r} \cdot \vec{z} = \sin \theta' \sin \Theta \sin \phi' + \cos \theta' \cos \Theta$$

where  $\vec{r}$  and  $\vec{z}$  are respectively the unit vectors of the incident radiance and the zenith directions.  $\bar{T}_b(\theta')$  is evaluated at each layer for all zenith angles  $\Theta'$  from the surrounding radiation. For the angular integrations, the model uses 16  $\theta$ -streams and 8  $\phi$ -streams on 0.125-km vertical grids. This configuration produces less than 1% error in the 200 GHz limb radiances under typical convective clouds.

Iterations for the  $T_{scat}$  calculation begin by first initializing all the *downward* radiances to 0 K and all the *upward* radiances to 300 K. Using the initial radiances,  $T_{scat}$  are evaluated with Eq.(A2) and then substituted into the RT Eq.(A1) to compute a new

set of *downward* and *upward* radiances. The next iteration repeats Eq.(A2) and Eq.(A1) calculations but with the new radiance set. The final equilibrium  $T_{scat}$  is obtained until convergence (0.1 K) is found. These source functions are evaluated independently for each cloud layer. Once all these source functions are finalized, they are incorporated into the RT equation for limb geometry to calculate limb radiances.

Figure A3a shows the limb radiance profiles calculated from a deep convective cloud with various *IWC*s. An ideal cloud profile model is used between 5-17 km where *IWC* decreases exponentially (~4-km scale height) with height. The *IWC* values labeled in the figure indicates the peak value at 5 km. The  $\Delta T_{cir}$  can saturate as the cloud becomes very thick. The  $\Delta T_{cir}$  –*IWC* relation at 100 hPa (Figure A3b) shows a near linear dependence at  $IWC < 40 \text{ mg/m}^3$  and saturation at  $IWC > 100 \text{ mg/m}^3$

## Figure Captions

Figure 1. UARS MLS 203-GHz radiances measured during (a) limb-scan and (b) limb-tracking operations. In the limb-scan case, most of the radiances are confined in the envelopes determined by clear-sky variability. Above  $\sim 12$  km tangent heights clouds are indicated by excess radiances above the clear-sky limit, whereas at lower tangent heights they show up as radiance depressions below the clear-sky limit. Clouds are not readily detectable at intermediate tangent heights (8-12 km for 203 GHz). In the limb-tracking case, clear- and cloudy-sky radiances show very different variations in terms of horizontal scale. The large short-scale radiance fluctuations near  $20^{\circ}\text{N}$ - $25^{\circ}\text{N}$  are indicative of cloud hits, whereas the more gradual radiance variations are likely due to water vapor and pointing variations. The periodic discontinuities along the orbit are caused by pointing corrections in maintaining 18-km limb tracking.

Figure 2. (a) Cloud-induced radiances  $\Delta T_{cir}$  obtained with the RT method from one day MLS observations. The imbedded box indicates the high- $h_t$  radiances that will be flagged as cloudy skies. As indicated by the sharp division between the numbers of points at  $\Delta T_{cir}=0$ , the RT method works reasonably well at  $P_{tan}$  up to  $\sim 200$  hPa but becomes less robust in the middle troposphere. (b) Histograms of the  $\Delta T_{cir}$  at 100 hPa in connection to clear-sky radiance bias and variability. Symbols represent the number of  $\Delta T_{cir}$  measurements in 1-K bins from six months of MLS data in early 1992 at latitudes between  $25^{\circ}\text{S}$  and  $25^{\circ}\text{N}$ . A Gaussian distribution is fitted to the clear-sky variability with the bias and standard deviation indicated in the plot. The number of cloudy-sky measurements drops off at large positive  $\Delta T_{cir}$  exponentially. The 3 K cloud flag threshold is indicated by the dashed line.

Figure 3. MLS cloud ice retrieval scheme.

Figure 4.  $hIWP-\Delta T_{cir}$  relations for 203-GHz limb radiance as calculated from the cloudy-sky RT model. The model uses the PSD parameterization in MH97 and assumes spherical ice particles for scattering calculations. The calculated  $hIWPs$  have been corrected for cloud self-extinction and air attenuation effects (see the text).

Figure 5. Cloud ice, water vapor and temperature maps at 100 hPa for January-March 1992. Top: MLS cloud occurrence frequency (colors) and NCEP temperature (contours). Middle: MLS  $IWC$  (colors) and  $H_2O$   $vmr$  (contours). Bottom: MLS  $IWC$  (colors) and  $RH_i$  (contours). Profiles contaminated by clouds are excluded in the water vapor and  $RH_i$  maps. The estimated  $IWC$  precision and bias for these maps are  $\sim 0.02$  and  $\sim 0.05$   $mg/m^3$  respectively.

Figure 6. As in Figure 5 but for July-September 1992.

Figure 7. The time series of (a) 100-hPa MLS cloud radiance, (b) 146-hPa MLS  $H_2O$   $vmr$ , (c) 100-hPa MLS  $H_2O$   $vmr$ , and (d) 100-hPa MLS  $RH_i$ . The cloud radiance is used to estimate  $IWC$  variations at 100 hPa. As described in section 3, the radiance can be approximately converted to 100-hPa  $IWC$  using the factor of  $1.5$   $mg/m^3/K$ . For the 100-hPa  $H_2O$   $vmr$  and  $RH_i$  results, cloudy profiles are excluded from the averaging. The white strips represent missing data. In the  $RH_i$  time series, sudden increases/decreases in value are likely the retrieval errors as  $RH_i$  becomes sensitive to temperature uncertainty at this level.

Figure A.1 Size dependence of  $IWC$  and volume scattering/extinction coefficients.  $N(r)$  is number density of ice particle as a function of radius and this bimodal PSD is from the MH97 parameterization for  $IWC=0.01$   $g/m^3$  and  $T=-60^\circ$ . The relative contribution of  $IWC$  and volume extinction/scattering coefficients ( $\beta_{c_e}/\beta_{c_s}$ ) from unit size bin, i.e.,  $dIWC/dr$  and  $d\beta_{c_e}/dr$  or  $d\beta_{c_s}/dr$ , have arbitrary units. For particles of size  $< 100$   $\mu m$  the volume extinction is dominated by ice absorption whereas it is mainly due to scattering if particle sizes are greater than  $100$   $\mu m$ .

Figure A.2 Diagram to illustrate the geometry of cloud scattering calculation in the limb RT model.

Figure A.3. (a) The 203-GHz radiance profiles calculated for deep convective clouds with different IWCs. (b) The calculated  $\Delta T_{\text{cir}}$ -IWC relation at 100 hPa. The dotted line shows the slope of  $1.5 \text{ mg/m}^3/\text{K}$  for  $\text{IWC} < 40 \text{ mg/m}^3$ . Optically-thick clouds cause the  $\Delta T_{\text{cir}}$  saturated to  $\sim 55 \text{ K}$ .

Figure 1. UARS MLS 203-GHz radiances measured during (a) limb-scan and (b) limb-tracking operations. In the limb-scan case, most of the radiances are confined in the envelopes determined by clear-sky variability. Above ~12 km tangent heights clouds are indicated by excess radiances above the clear-sky limit, whereas at lower tangent heights they show up as radiance depressions below the clear-sky limit. Clouds are not readily detectable at intermediate tangent heights (8-12 km for 203 GHz). In the limb-tracking case, clear- and cloudy-sky radiances show very different variations in terms of horizontal scale. The large short-scale radiance fluctuations near 20°N-25°N are indicative of cloud hits, whereas the more gradual radiance variations are likely due to water vapor and pointing variations. The periodic discontinuities along the orbit are caused by pointing corrections in maintaining 18-km limb tracking.

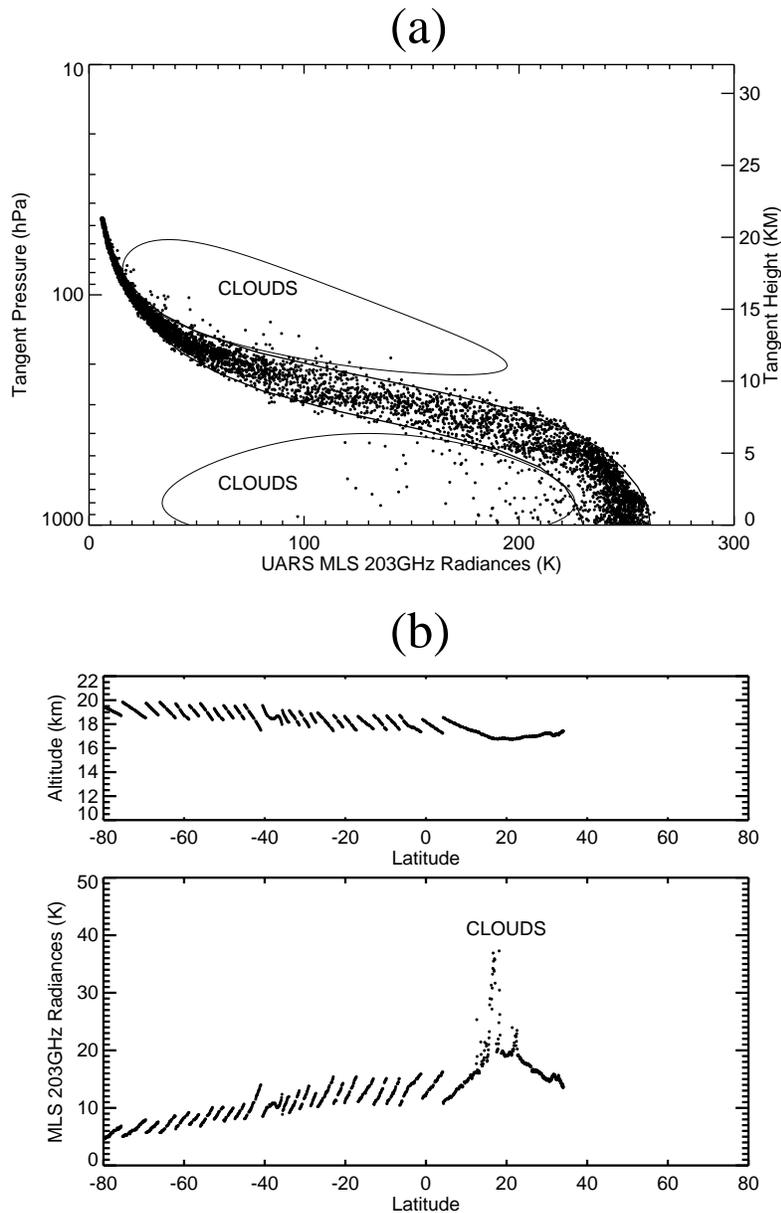

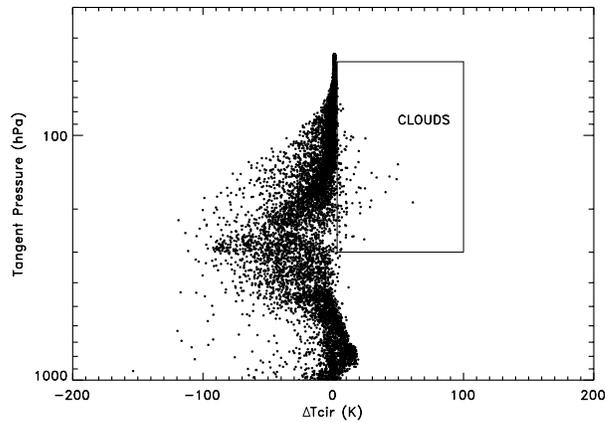

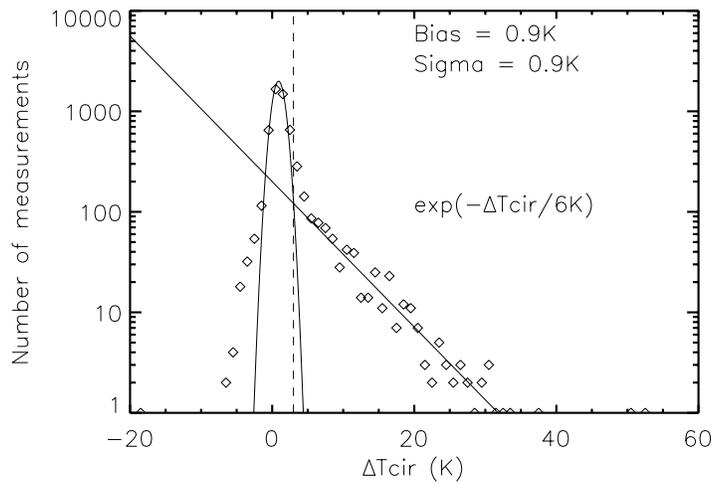

Figure 2. (a) Cloud-induced radiances  $\Delta T_{\text{cir}}$  obtained with the RT method from one day MLS observations. The imbedded box indicates the high- $h_t$  radiances that will be flagged as cloudy skies. As indicated by the sharp division between the numbers of points at  $\Delta T_{\text{cir}}=0$ , the RT method works reasonably well at  $P_{\text{tan}}$  up to  $\sim 200$  hPa but becomes less robust in the middle troposphere. (b) Histograms of the  $\Delta T_{\text{cir}}$  at 100 hPa in connection to clear-sky radiance bias and variability. Symbols represent the number of  $\Delta T_{\text{cir}}$  measurements in 1-K bins from six months of MLS data in early 1992 at latitudes between  $25^\circ\text{S}$  and  $25^\circ\text{N}$ . A Gaussian distribution is fitted to the clear-sky variability with the bias and standard deviation indicated in the plot. The number of cloudy-sky measurements drops off at large positive  $\Delta T_{\text{cir}}$  exponentially. The 3 K cloud flag threshold is indicated by the dashed line. False cloud detection is described by the portion of the Gaussian distribution with  $\Delta T_{\text{cir}} > 3$  K and causes a bias of 0.03 K in  $\Delta T_{\text{cir}}$  and 0.9% in cloud occurrence frequency at 100 hPa.

Figure 3. MLS cloud ice retrieval scheme

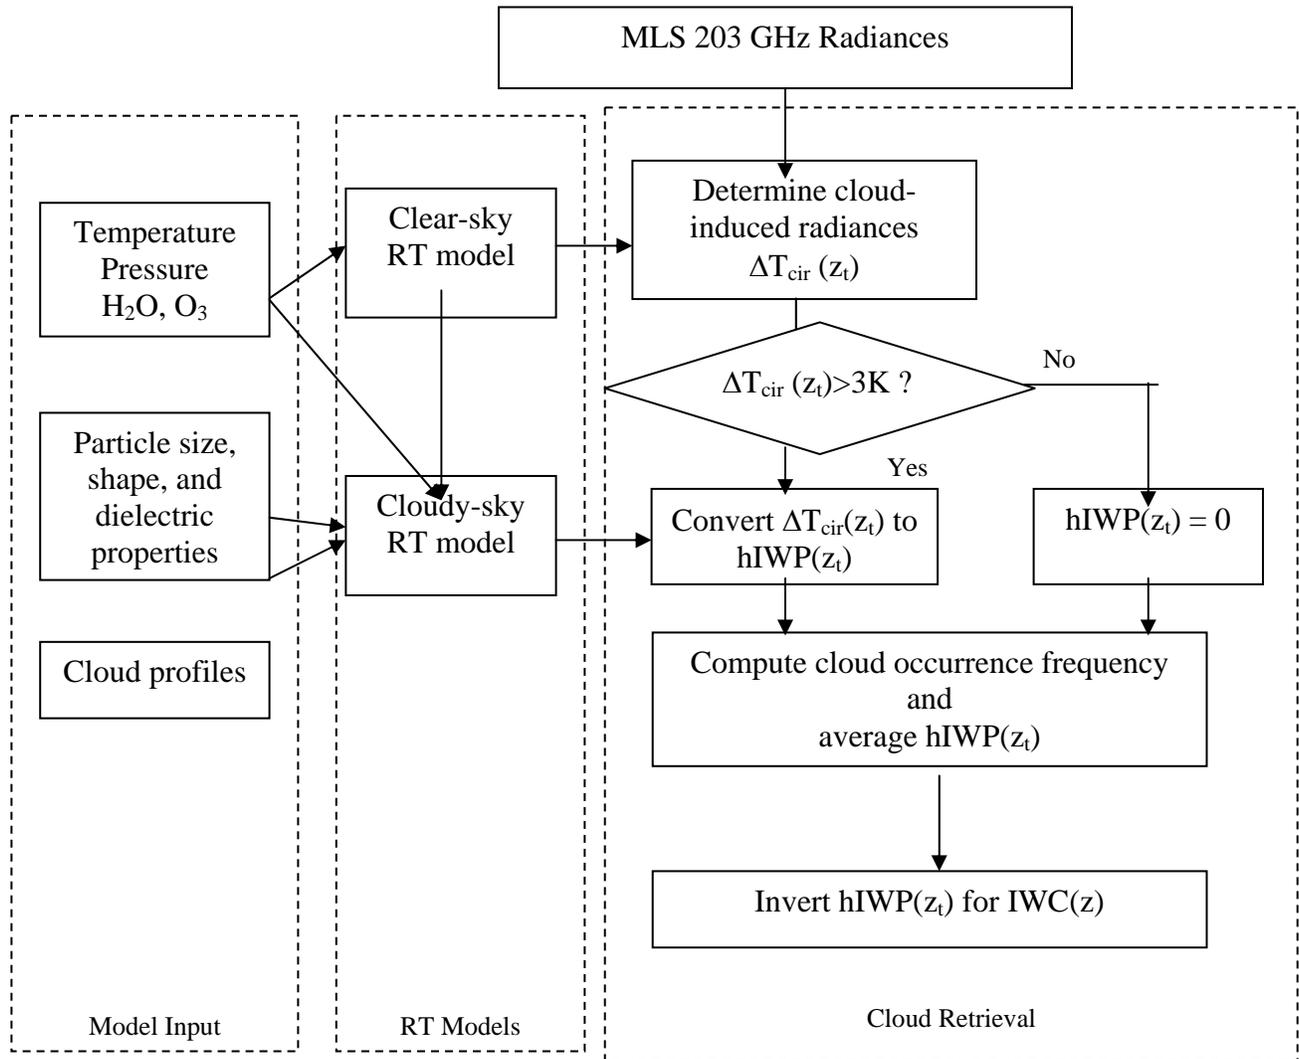

Figure 4. The calculated  $hIWP-\Delta T_{cir}$  relations for MLS 203-GHz radiance using the cloudy-sky RT model. For scattering calculations the model assumes the PSD parameterization given in MH97 and spherical ice particles. The calculated  $hIWP$ s have been corrected for cloud self-extinction and air attenuation effects (see the text).

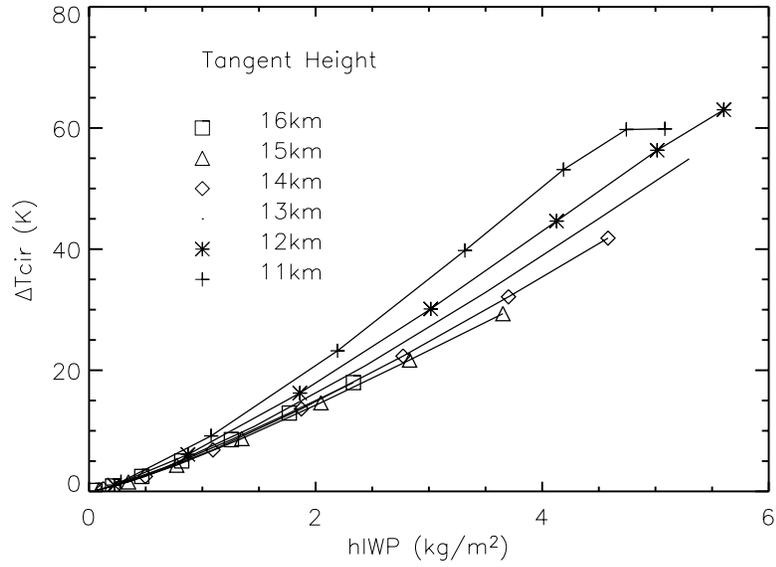

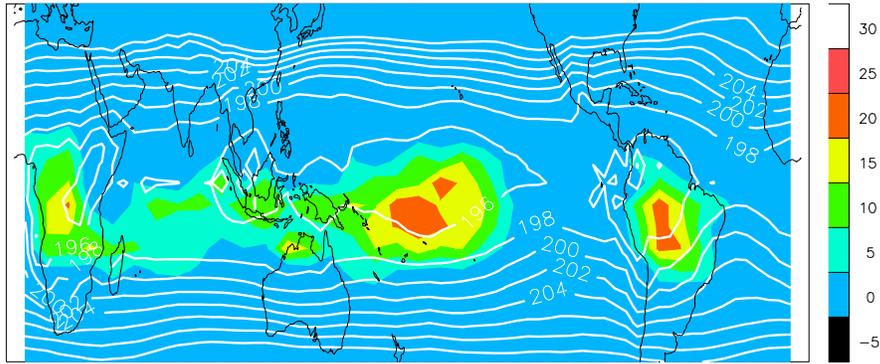

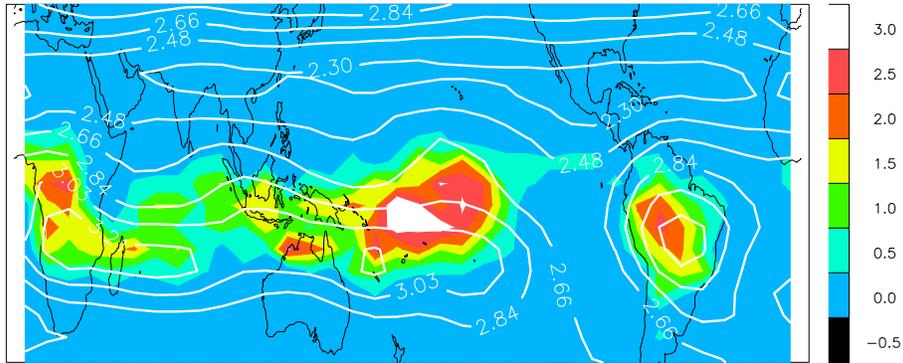

Figure 5. Cloud ice, water vapor and temperature maps at 100 hPa for January-March 1992. Top: MLS cloud occurrence frequency (colors) and NCEP temperature (contours). Middle: MLS IWC (colors) and H<sub>2</sub>O vmr (contours). Bottom: MLS IWC (colors) and RH<sub>i</sub> (contours). Profiles contaminated by clouds are excluded in the water vapor and RH<sub>i</sub> maps. The estimated IWC precision and bias in these maps are  $\sim 0.02$  and  $\sim 0.05$  mg/m<sup>3</sup> respectively.

Cloud Occur. Freq. (% in color) vs. NCEP Temp. (K in contour)

IWC (mg/m<sup>3</sup> in color) vs. Water Vapor (ppmv in contour)

IWC (mg/m<sup>3</sup> in color) vs. RH<sub>i</sub> (% in contour)

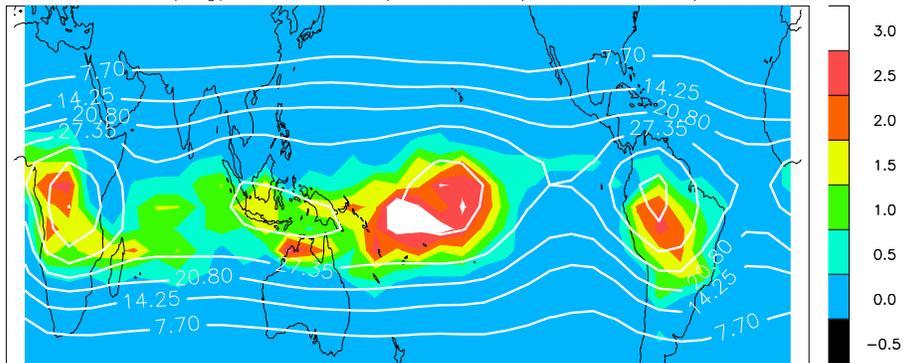

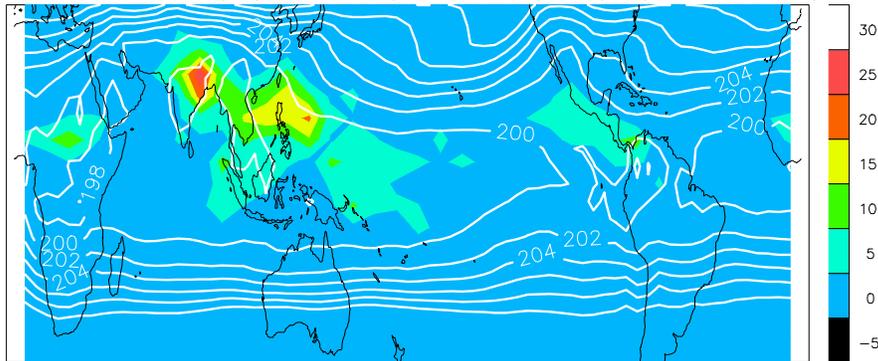

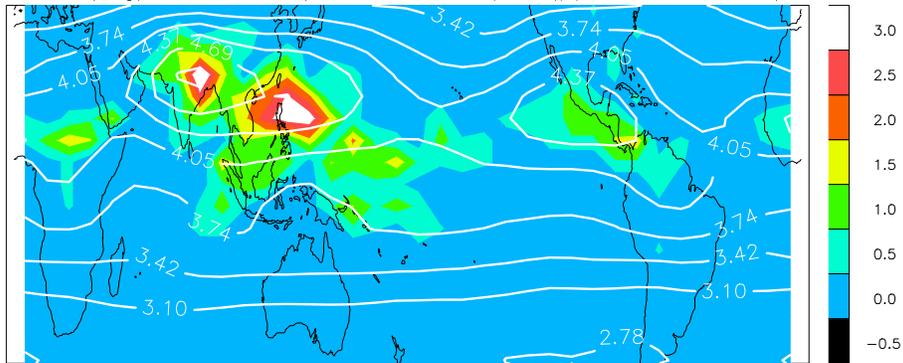

Figure 6. As in Figure 5 except for July-September 1992.

Cloud Occur. Freq. (% in color) vs. NCEP Temp. (K in contour)

IWC ( $\text{mg}/\text{m}^3$  in color) vs. Water Vapor (ppmv in contour)

IWC ( $\text{mg}/\text{m}^3$  in color) vs. RH<sub>i</sub> (% in contour)

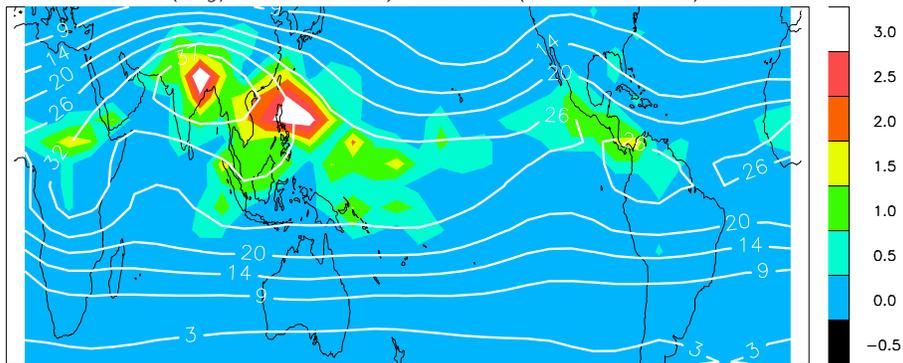

Figure 7. The time series of (a) 100-hPa MLS cloud radiance, (b) 146-hPa MLS H<sub>2</sub>O vmr, (c) 100-hPa MLS H<sub>2</sub>O vmr, and (d) 100-hPa MLS RH<sub>i</sub>. The cloud radiance is used to estimate IWC variations at 100 hPa. As described in section 3, the radiance can be approximately converted to 100-hPa IWC using the factor of 1.5 mg/m<sup>3</sup>/K. For the 100-hPa H<sub>2</sub>O vmr and RH<sub>i</sub> results, cloudy profiles are excluded from the averaging. The white strips represent missing data. In the RH<sub>i</sub> time series, sudden increases/decreases in value are likely the retrieval errors as RH<sub>i</sub> becomes sensitive to temperature uncertainty at this level.

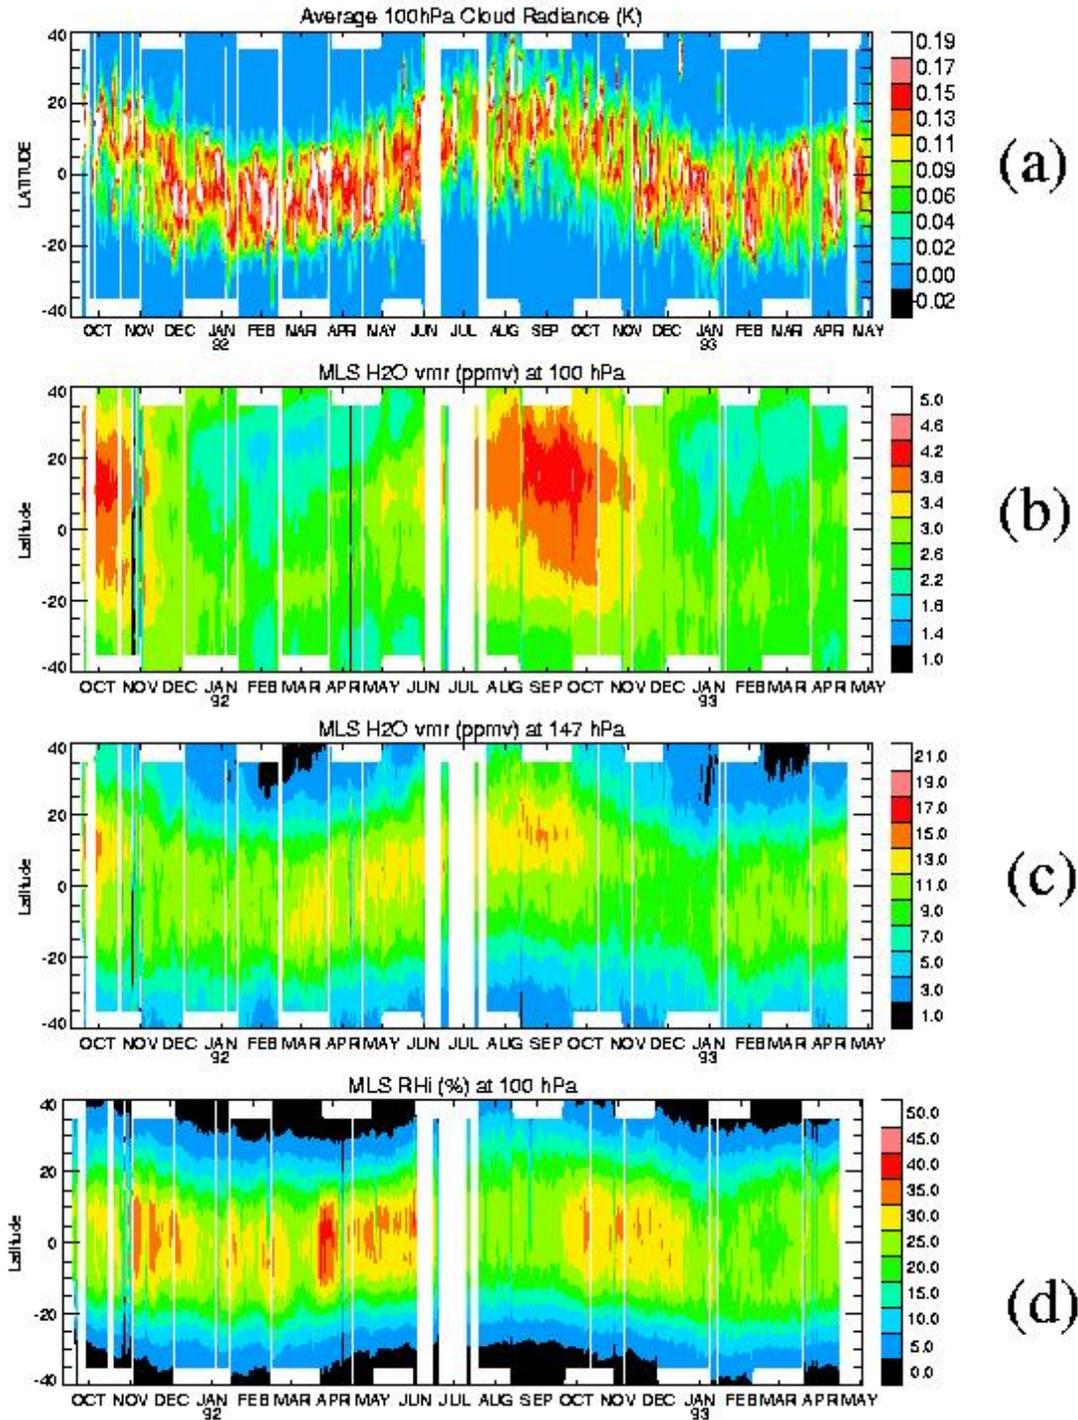

Figure A.1 Size dependence of *IWC* and volume scattering/extinction coefficients.  $N(r)$  is number density of ice particle as a function of radius and this bimodal PSD is from the MH97 parameterization for  $IWC=0.01 \text{ g/m}^3$  and  $T=-60^\circ$ . The relative contribution of *IWC* and volume extinction/scattering coefficients ( $\beta_{c_e}/\beta_{c_s}$ ) from unit size bin, i.e.,  $dIWC/dr$  and  $d\beta_{c_e}/dr$  or  $d\beta_{c_s}/dr$ , have arbitrary units. For particles of size  $< 100 \mu\text{m}$  the volume extinction is dominated by ice absorption whereas it is mainly due to scattering if particle sizes are greater than  $100 \mu\text{m}$ .
